Abstract

Background: Posterior fossa tumours is one of the most common tumours in pediatrics. The most common tumours include juvenile pilocytic astrocytoma. Differential diagnosis of pediatric brain tumours begins with accurate localization of the site of origin the tumours, which is the most important diagnostic features, Conventional MRI with contrast study remains the gold standard for evaluation of brain tumours.

Aim of Study: Is to assess role of MRI in evaluation of space occupying lesions seen at the posterior fossa in pediatric age group.

Patients and Methods: This retrospective study, including 40 children with their age ranging between 2 and 10 years. All the forty patients were examined by; axial T1 WI, axial T2 WI, coronal and axial FLAIR, post contrast T1WI was done after injection of Magnevist (0.1ml/Kg); DW images and ADC maps were acquired.

Results: MRI study revealed 16 cases diagnosed as medulloblastoma (40%), 8 cases as Ependymoma (20%), 8 cases as juvenile pilocytic astrocytoma (20%), 6 cases as pontine Glioma (15%) and 2 cases as Schwannoma (5%).

Conclusion: Conventional MRI with DWI & ADC has high accuracy in the differentiation of posterior fossa tumours in pediatrics.

Key Words: Posterior fossa – Pediatric – MRI – Juvenile pilocytic astrocytoma – Medulloblastoma – Ependymoma – Schwannoma – Brainstem glioma.

Introduction

POSTERIOR fossa tumours account for 45-60% of all pediatrics tumours, the most common tumours include juvenile pilocytic astrocytoma (JPA) which is the most common pediatric benign cerebellar neoplasm, medulloblastoma, ependymoma, and brain stem glioma are also common tumours [1,2], oligodendroglioma is a rare pediatric low grade, slowly growing cerebral hemispheric tumour and account for only about 1% [3]. Medulloblastoma

is the most common malignant cerebellar tumours in pediatric, these tumours have aggressive course with tendency of CSF dissemination and fatal outcome [4]. Ependymoma is the third posterior fossa tumours and arising from the floor of the fourth ventricle with a peak incidence between 3 to 5 years [5]. Brainstem gliomas comprise approximately 10-20% of all intracranial tumors in children with age incidence less than 10 years [6]. Differential diagnosis of pediatric brain tumours begins with accurate localization of the site of origin the tumours, which is the most important diagnostic features, Conventional MRI with contrast study remains the gold standard for evaluation of brain tumours, it helps in the assessment of location, and extent of the tumour, recent studies evaluated the role of diffusion weighted image in differentiating grade and type of pediatric brain tumours in the posterior fossa [1,7,8].

Patients and Methods

This retrospective study was conducted according to the guidelines of the ethics committee of Tanta university and was approved by our institutional review board; all child parents gave us written informed consent. This retrospective study was done between August 2015 and February 2017 including 40 children with their age ranging between 2 and 10 years, (mean 4 ± 1), 24 males (60%) and 16 females (40%). Complaining of headache, blurring of vision, squint, ataxia, cranial nerve palsy and symptoms of increased intracranial tension.

Image protocol:

All examinations were performed using a 1.5 T MR Unit (SIGNA Horizon, General Electric Medical System, Milwaukee, WI) using head coil.

Abbreviation:

JPA: Juvenile pilocytic astrocytoma.

Correspondence to: Dr. Mahmoud A. Dawood,
The Department of Radiology & Neurosurgery,
College of Medicine, Tanta University, Tanta, Egypt

MRI protocol:

All the twenty patients were examined by; axial T1 WI (TR/TE: 400-600/10-20m/sec.), axial T2 WI (TR/TE: 2000-4000/ 100-120m/sec.), coronal and axial FLAIR (TR/TE/TI: 4000-6000/1 40/1200m/sec.), post contrast T1WI was done after injection of Magnevist (0.1ml/Kg); slice thickness: 5mm, the matrix was 256x256 and the field of view was 220-240mm.

Diffusion weighted imaging with apparent diffusion coefficient calculation:

DW images were obtained by using an axial echo-planar SE sequence, average, 5mm section thickness. DW images and ADC maps were acquired by using b values of 0 and 1000s/mm². Post processing of ADC maps was performed. Standard mean ADC values were calculated automatically and expressed in 10⁻³mm²/sec.

Histopathology is our gold standard.

Statistical analysis:

Statistical analysis were undertaken to prove the efficacy of MRI & diffusion in the evaluation of posterior fossa brain tumors. Statistical analysis were performed using the SPSS software package version 16.0 (statistical package for social science TM) and *p*<0.05 was considered to be statistically significant. The sensitivity, specificity for each protocol were compared in order to evaluate the reliability of each of them & when they are combined.

Results

In this retrospective study, forty patients (24 (60%) male & 16 ranged (40%) females with their age ranges from 2 to 10 years), (Table 1, Figs. 1,2) have posterior fossa tumours with the postoperative pathological reports, was included in this study. The patients' complaint shown in Table (2) & Fig. (3).

Other MRI findings noted in the studied group include; Hydrocephalus was the most common association especially in cases of medulloblastoma followed by cystic changes which were noted in all cases of juvenile pilocytic astrocytoma, hemorrhage and necrosis were also noted especially in cases of medulloblastoma (Table 4).

The signal intensities on MRI were low SI in T1 WI 28 cases (70%), 4 cases (10%) showed intermediate SI and 4 cases (10%) showed high SI, on T2 WI and FLAIR sequence 36 case (90%) showed high SI while only 4 cases showed intermediate SI (Table 4 & Fig. 5) & (Table 5).

Fig. (6)

DWI was significantly restricted in cases of medulloblastoma with ADC value ranging from 0.5 to 0.8x10⁻³ mm²/s., in juvenile pilocytic astrocytoma the cystic component appeared hypointense on DWIs compared to normal appearing brain parenchyma, denoting free diffusion. Their ADC values ranged from 2.1-2.9x10⁻³ mm²/s. The solid mural nodule of the tumor displays iso-to hypointense signal on DWI (b1000) and iso to hyperintense signal on ADC map denoting free diffusion, the ADC value was between 1.4 and 1.9x10⁻³ mm²/s. In cases of ependymoma, the signal inten-

sity was heterogeneous on both DWI and ADC map due to the presence of solid and cystic components. The solid enhanced component displayed iso-to slightly hyperintense signal on DWI, hypointense signal on ADC map and had ADC value between 1.01 and 1.3x10⁻³ mm²/s suggesting restricted diffusion more than that seen in JPA cases. In brain stem Glioma the signal intensity was hypointense on DWI compared to normal brain parenchyma denoting free diffusion, one case show heterogeneous signal intensity in DWI and ADC map denoting high grade of anaplasia with ADC value ranging from 1.1 x 10⁻³ to 1.4x 10⁻³. In Schwannoma the signal intensity was hypointense on DWI and hyperintense on ADC map with ADC value 1.6x10⁻³ denoting free diffusion. It also was found that lower ADC values were consistent with more malignant lesions as in medulloblastoma where higher ADC values were found in benign lesions as in Juvenile pilocytic astrocytoma. Table (8), Fig. (7) showed the distribution of patient characteristics according to MRI diagnosis. Table (9) revealed the Histopathological Diagnosis of patients: Tables (10,11,12) demonstrated the comparison between MRI diagnosis and histopathological diagnosis.

A- Axial T 1 WI.

B- Axial T2WI.

C- Axial FLAIR.

D- Axial T 1 WI+contrast.

H- Diffusion WI.

I- ADC image.

Fig. (7): Male patient aged 9 years old complaining of squint.

MRI: Large space occupying lesion involving most of pons (mainly to the right side) measures 4x4.5x5.5cm displaying low signal intensity in T1WI with small areas of subacute hemorrhage within (A), high signal intensity in T2WI (B) and FLAIR (C) sequences with extrinsic cystic parts within, the mass show heterogeneous patchy contrast enhancement after IV contrast injection (D), the mass encroaching upon the right cerebello pontine cistern with mild compression and displacement of the fourth ventricle to the left side with no significant supra tentorial hydrocephalic changes. Picture is suggestive of pontine glioma with hemorrhagic component.

DWI: The lesion show small areas of restricted diffusion. (H).

ADC values: Lesion measured $0.4 \times 10^{-3} \text{ mm}^2/\text{s}$ (I).

Perilesional edema: Measured $0.7 \times 10^{-3} \text{ mm}^2/\text{s}$.

Fig. (8): Female patient 4 years old complaining of persistant headache.

MRI: Abnormal space occupying lesion is seen at the right cerebellar hemisphere measures 4x4.6cm displaying low signal in T1WI (A), high signal in T2WI (B) & FLAIR (C), intense homogenous enhancement after IV contrast injection (D)&(E) surrounded by cystic parts displaying low signal in T1 WI and high signal in T2 WI (CSF like signal) (F) exerting mass effect in the form of compression of sulci and cistern and fourth ventricle causing supratentorial hydrocephalus in the form of dilated third and lateral ventricle picture is suggestive of medulloblastoma with supratentorial hydrocephalus.

DWI: The lesion appeared with restricted diffusion. (I)

ADC values (J): $0.8 \times 10^{-3} \text{ mm}^2/\text{s}$ with perilesional area ADC value measured $0.9 \times 10^{-3} \text{ mm}^2/\text{s}$

Histological examination: Revealed that the lesion is medulloblastoma.

A- Axial T1WI.

B- Sagittal T2WI.

C- Axial FLAIR.

D- Axial T 1 WI+contrast.

E- Sagittal T1WI+contrast.

F- DWI.

Fig. (9): Female patient aged 12 years complaining of headache and blurring of vision. Eman (pilocytic astrocytoma).

MRI: Large cystic mass with superficial solid mural nodule is seen in the posterior fossa centered upon the right cerebellar hemisphere, its solid part display isointense signal in T1 WI (A), hyperintense signal in T2 WI (B) and FLAIR (C), with bright enhancement after Gd administration (D) and (E), the mass exert mass effect in the form of compression of the fourth ventricle as well as pons and effacement of prepontine cistern associated with moderate dilatation of supratentorial ventricular system with trans ependymal retrograde CSF permeation.

DWI: Free diffusion is seen in DWI.

ADC values: $1.2 \times 10^{-3} \text{ mm}^2/\text{s}$ (I).

The above MRI and DWI & ADC picture: Are in favor of pilocytic astrocytoma.

B- Coronal T2.

C- Sagittal FLAIR.

D- Axial T 1 WI+contrast.

H- Diffusion WI.

I- ADC image.

Fig. (10): Female patient aged 8 years old known to have cerebral palsy since birth.

MRI: Large posterior fossa mass is seen arising from the fourth ventricle measures 3x3.5x3.7cm displaying low SI in T1 WI (A) and high SI in T2 WI (B) and FLAIR with central foci of signal heterogeneity representing necrosis (C), the mass show heterogeneous enhancement after IV contrast injection (D) with moderate dilatation of the fourth ventricle around the mass and supratentorial hydrocephalus.

DWI: The lesion showed free diffusion (H).

ADC values: $1.5 \times 10^{-3} \text{ mm}^2/\text{s}$ (I).

Discussion

Conventional MRI is an essential tool for diagnosis and evaluation of posterior fossa tumours in pediatrics [9]. DW image helped in differentiating grades and types of pediatric brain tumours in the posterior fossa [10]. This study was encountered on forty cases, 24 male and 16 females, their age ranged from 2 to 10 years. The most common clinical presentation in our group of patients was headache and vomiting, which was in agreement with the study of LIN & Riva [11].

According to conventional MRI findings, the most common pediatric posterior fossa tumors encountered in our study were medulloblastoma (16 cases), pilocytic astrocytoma in (8 cases), ependymoma in (8 cases), diffuse pontine glioma in (6 cases) and Schwannoma only in (2 cases), which disagree with Cascone et al., [2].

As regard the site from which the tumour arise, all cases of pilocytic astrocytoma were seen located near the mid line arising from cerebellum as well-circumscribed, cystic like masses with a soft tissue mural nodule which was in agree with Kelly K. et al., [12], while in medulloblastoma 10 cases were located at cerebellar vermis and 6 cases located at cerebellar hemisphere which was in agree with Fruehwald-Pallamar et al., [13], in cases of glioma all cases were of diffuse pontine glioma which was in agree with Donaldson S., et al., [14].

The most common other MRI association was hydrocephalus which was present in 22 cases, 10 of them were medulloblastoma (55%), the other findings were cystic changes present in 14 cases, 8 of them were juvenile pilocytic astrocytoma cases (35%) and hemorrhage present in 8 cases, three of them were medulloblastoma (20%), this was in agree with Reddy et al., [15].

The pattern of enhancement in our studied patients was, heterogeneous enhancement in 12 cases of medulloblastoma while the other four cases showed homogenous enhancement, this was in agree with Eran A. et al., [16]. In cases of Ependymoma, the eight cases showed heterogeneous enhancement, in JPA all solid nodules showed homogenous enhancement and in pontine glioma two cases showed heterogeneous enhancement, two cases, faint enhancement and the last, no enhancement, while in case of Schwannoma homogenous intense enhancement was seen, this was in agreement with Mauffrey [17].

As regards DWI & ADC maps, there was a difference in ADC value between JPA and medulloblastoma. It was higher than $1.3 \times 10^{-3} \text{ mm}^2/\text{s}$ in JPA cases while in medulloblastoma, ranged between 0.55 and $0.9 \times 10^{-3} \text{ mm}^2/\text{s}$, (malignant lesion) which was in consistent with the study of Rumboldt et al., [18], as they concluded that significant differences in cellularity of pediatric cerebellar neoplasms, particularly between JPAs and medulloblastoma indicate that these lesions could potentially be distinguished by their ADC values, used cut off values of more than $1.4 \times 10^{-3} \text{ mm}^2/\text{s}$ for JPA and less than $0.9 \times 10^{-3} \text{ mm}^2/\text{s}$ for medulloblastoma.

In ependymoma, all cases showed heterogeneous signal in DWI and ADC map with ADC value ranging from 1.01 and $1.3 \times 10^{-3} \text{ mm}^2/\text{s}$ suggesting restricted diffusion more than that seen in JPA cases consistent with Yamasaki et al., [19].

In cases of pontine Glioma, it was hypointense on DWI compared to normal brain parenchyma denoting free diffusion, some cases showed heterogeneous signal intensity in DWI and ADC map denoting high grade of anaplasia with ADC value ranging from 1.1×10^{-3} to 1.5×10^{-3} which was consistent with the study of Lobel et al., [20].

In cases of Schwannoma, the signal intensity was hypointense on DWI and hyperintense on ADC map compared to normal parenchyma denoting free diffusion, with ADC value of 1.6×10^{-3} which was in agreement with the study of with Beaman et al., [21].

From our results, Conventional MRI had successfully diagnosed 32 cases, 10 cases as medulloblastoma, 8 cases as juvenile pilocytic astrocytoma, 6 cases as glioma, 6 cases as ependymoma and 2 cases as Schwannoma. DWI & ADC values had correctly diagnosed 16 cases as medulloblastoma, 8 cases as juvenile pilocytic astrocytoma, 8 cases as ependymoma, 6 cases as pontine glioma and 2 cases as Schwannoma.

By comparing MRI findings with histopathology it was found that conventional MRI combined with DWI and ADC values showed sensitivity of 94% which is statistically significant positive strong correlation between MRI diagnosis and Histopathological confirmation.

Conclusion:

Conventional MRI with DWI & ADC has high accuracy in the differentiation of posterior fossa tumours in pediatrics.

دور الرنين المغناطيسي في تشخيص أورام الحفرة الخلفية للمخ في الأطفال

تمثل أورام الحفرة المخية في الأطفال حوالي ٦٥٪ من مجموع أورام الأطفال والتي تختلف اختلافاً واضحاً عن الأورام التي تحدث في البالغين وتستخدم الأشعة المقطعية والرنين المغناطيسي وكذلك عمر المريض في التنبؤ بشكل موثوق من نوع الورم في أكثر من ٧٠٪ من الحالات.

الحفرة الخلفية في المخ تمثل حيزاً ضيقاً والذي يحاط من جميع الجهات بالام الجافية ويمثل جذع المخ والمخيخ والبطين الرابع ولذلك فإن أى ورم في هذه المنطقة قد يؤثر بشكل سلبي على هذه الأعضاء الحيوية بالجسم ولذلك لابد من تشخيص دقيق لمكان وامتداد الورم وتأثيره على المناطق المحيطة كما أن أورام الحبل الشوكي قد تمتد إلى جذع المخ مما قد يؤثر في وظيفته.

ولأن الأشعة المقطعية لها بعض القيود في تشخيص هذه الأورام والتي تتمثل في صعوبة تحديد المكان بدقة وتأثيره على المناطق المحيطة المهمة في المخ وتأثيرها على الأوعية الدموية في ذلك المكان كان لابد من استخدام وسيلة أكثر دقة في التشخيص قبل التدخل الجراحي.

ولذا يستخدم الرنين المغناطيسي في تشخيص أورام الحفرة الخلفية في المخ وكذلك تحديد تأثيره على المناطق المحيطة ولكن قد يواجه بعض الصعوبات في تحديد نوع الورم ودرجة انتشاره ولذلك لابد استخدام أبحاث أخرى للتشخيص الدقيق.

الدراسات الحديثة تقيم دور تصوير الرنين المغناطيسي عن طريق دراسة الحركة البراونية لجزيئات الماء في أنسجة المخ للتمييز بين الدرجات والأنواع المختلفة لأورام الحفرة الخلفية للمخ في الأطفال وكذلك دراسة الخصائص الفيزيائية للأورام مما يساعد في تشخيص أدق قبل التدخل الجراحي.

وقياس معامل الإنتشار الواضح وهو مقياس لحجم انتشار جزيئات الماء داخل الأنسجة يفيد في توضيح نوع الورم وكمية الماء بداخله والتي تختلف من ورم لآخر ويعتمد معامل انتشار الماء في الخلايا الحية على نسبة الماء داخل الخلايا وخارجها.

والهدف من هذه الدراسة هي بحث ودراسة دور الرنين المغناطيسي وحساب قيمة معامل الانتشار الظاهري في تشخيص أورام الحفرة الخلفية للمخ في الأطفال وقد أجريت هذه الدراسة على ٢٠ حالة من أطفال تتراوح أعمارهم من شهور إلى ١٦ سنة من كلا الجنسين وقد خضع جميع المرضى للتقييم بالتاريخ المرضي الكا مل والفحص العام والفحص العصبي، وكذلك التقييم الإشعاعي بواسطة التصوير بالرنين المغناطيسي، وتمت مقارنة نتائجهم مع التحليل النسيجي المرضى ووجدنا النتائج التالية:

ورم النخاع هو ورم الحفرة الخلفية الأكثر شيوعاً في هذه الدراسة تليها إبنديموما ونجمي خلية نجمي في حين كان الورم الحبيبي ورم شفاني الأقل.

وبحساب قيمة معامل الانتشار وجد أنه الأدق والاسهل في التفرقة بين مختلف الاورام حيث وجد أن القيمة الأكبر من 1.0×10^{-3} - 3 مميز للورم الخلية النجمي والقيمة الأقل من 1.0×10^{-3} - 3 مميز لورم النخاع.
